### Effect of Ripple Loads on Stress-Corrosion Cracking in Structural Steels

P.S. Pao and R.A. Bayles

Naval Research Laboratory, Washington, DC 20375-5343

#### ABSTRACT

If very small amplitude cyclic (or "ripple") loads perturb an otherwise constant load condition in an aggressive environment, life prediction based solely on the static stress-corrosion cracking threshold ( $K_{ISCC}$ ) may prove nonconservative, as the ripple-load effect may produce fracture in a structural alloy at stress-intensity levels less than 50% of  $K_{ISCC}$ . Ripple-load cracking has been successfully treated as an extreme case of corrosion fatigue. A predictive framework for such ripple-loading effects (RLE) is developed from concepts and descriptors used in SCC and corrosion fatigue characterization. The proposed framework is capable of defining critical conditions required for the occurrence of RLE and predicting time-to-failure curves. A new threshold parameter,  $K_{IRLC}$ , which defines the threshold stress-intensity factor below which ripple-load cracking will not occur, is identified to ensure fail-safe life even in the presence of the ripple effect. A "window" for ripple-load cracking susceptibility, bounded by  $K_{IRLC}$  and  $K_{ISCC}$ , defines the critical conditions for ripple-load cracking. The predicted ripple-load cracking time-to-failure curves agree well with experimental measurements. From studies of several steels, it is found that 5Ni-Cr-Mo-V steel (HY-130) and TLP tendon pipe steel, both of which exhibit good stress-corrosion cracking resistance, are prone to degradation by the ripple effect.

KEY WORDS : crack propagation, ripple-load cracking, stress-corrosion cracking, corrosion fatigue, steels, tension leg platform

## 1.0 INTRODUCTION

Stress-corrosion cracking (SCC) is a cracking process caused by the conjoint action of stress and a corrodent [1]. Conceptually, SCC will occur if a sensitive material is exposed to a corrosive environment under sufficient stress for a sufficient length of time. For a structural material which contains a crack or crack-like defect, the resistance to SCC is normally evaluated in terms of the fracture mechanics parameter,  $K_{ISCC}$ , the threshold stress-intensity factor below which crack extension will not occur. The measurement of  $K_{ISCC}$  and its application to design of structures for the marine environment commonly presumes sustained or constant load conditions. However, in the real world, a constant load condition is rarely attainable. For example, the loading profiles experienced by offshore platform structures most likely involve the superposition of relatively small amplitude cyclic load perturbations on a substantially larger constant load. Though such perturbations might at first glance seem virtually insignificant on the basis of their amplitude, preliminary study has shown that their effect, described as the "ripple effect" by Speidel [2], can be sizable. An example of a ripple-load profile is schematically shown in Fig. 1. Recent work at the Naval Research Laboratory on steels, titanium, and aluminum alloys has suggested that the presence of such ripple loads can significantly reduce the apparent SCC threshold and can shorten the life of a structure [3-8]. Others have also observed that small fluctuating loads may produce SCC at significantly lower stresses than those required under purely static loads [9-18]. Thus, a design based solely on the static  $K_{ISCC}$  without proper consideration of the ripple-load effect (RLE), may be nonconservative.

The objective of this study is to develop an understanding of RLE and the framework required for the prediction of RLE. First of all, RLE is investigated in two different classes of steels: the medium strength, high toughness 5Ni-Cr-Mo-V steel and tension leg platform (TLP) tendon pipe steel (0.06C, 0.2Si, 0.21Cu, 0.2Ni, Bal Fe), and the high strength, low toughness AISI 4340 steel. Secondly, the critical conditions required for a material to exhibit RLE in marine

environment are defined and quantitative prediction of the maximum extent of degradation by RLE is presented. A new ripple-load cracking threshold,  $K_{IRLC}$ , which marks the onset of ripple-load crack growth, has been devised and is offered as an alternative design parameter to represent the upper bound of the design limit. And finally, the quantitative predictive methodology for time-to-failure curves associated with ripple-load cracking is offered for a given combination of material and loading conditions.

## 2.0 MATERIALS AND EXPERIMENTAL PROCEDURES

### 2.1 Materials

The three steels studied in this investigation were TLP tendon pipe steel, 5Ni-Cr-Mo-V steel, and AISI 4340 steel. The chemical analysis and the tensile properties are given in Tables 1 and 2, respectively.

### 2.2 Ripple-Load "Direct Experiments"

Figure 2 shows the design of the "direct experiment" used to evaluate the effect of ripple loading on steels. The apparatus is a cantilever bend load frame, modified with a motorized cam to superimpose a small oscillating load onto the dead-weight load.

The specimens were fatigue-precracked in air, then the environment cup was sealed to the specimen. After the specimen was mounted in the load frame, the cup was filled with 3.5% NaCl solution. After 24 hours a dead-weight load was gradually applied while a crack mouth opening gage was used to determine, by means of compliance, the crack depth. Enough load was then applied to produce the desired  $K_{max}$ . The eccentric cam and spring apparatus was set up to cyclically reduce the load by the desired amount - in the case described here 10% ( $R=0.90$ ) of the dead-weight load. The cam motor was switched on to begin the experiment. A cyclic frequency of 0.1 Hz (6 cpm) was used to simulate ocean wave motion. Evaporation losses were made up with distilled water as needed and the saltwater was replaced weekly.

For 5Ni-Cr-Mo-V and AISI 4340 steel, time-to-failure data under SCC and ripple-load conditions were determined using precracked cantilever-beam specimens of length  $L=400$  mm, width  $W=50.8$  mm and thickness  $B=25.4$  mm, with an initial (normalized) crack length of  $a/W=0.5$  and sidegrooves of depth 1.25 mm per side. All tests were conducted at ambient temperature. The

AISI 4340 steel was tested at the freely corroding potential. The 5Ni-Cr-Mo-V steel was tested at a potential of approximately -1.0 V obtained by coupling to zinc anodes.

### 2.3 Corrosion-Fatigue Tests

For TLP tendon pipe steel, fracture mechanics type specimens were machined from the base metal region and from the weld region of 609.6 mm (24") O.D. TLP tendon pipe with a wall thickness of 20.6 mm. For weld region specimens, as shown in Fig. 3, the starter notch was located at the center of the fusion zone and the intended crack-growth direction was parallel to the welding direction (circumferentially). Time-to-failure data under SCC and ripple-load conditions were determined in the weld region and in the base metal using precracked compact-tension specimens of width  $W=31.5$  mm and thickness  $B=15.1$  mm, with sidegrooves of depth 0.8 mm per side. To simulate a ripple-load condition and to measure threshold levels of stress-intensity range directly, precracked specimens were cyclically loaded using a corrosion-fatigue apparatus which is shown schematically in Fig. 4. Tests were conducted at either room temperature (20 °C) or 3 °C (to simulate deep water temperature) in a 3.5% NaCl solution with a stress ratio (minimum: maximum) of  $R = 0.90$ , a haversine waveform, and a cyclic frequency of 5 Hz. SCC thresholds were determined in the 3.5% NaCl solution using constant load cantilever bend bar tests. The TLP tendon pipe steel was tested at a potential of -0.9 V. Crack lengths were determined using a compliance related CMOD technique. Details of the experimental procedures have been published elsewhere [3, 6-8, 19].

The method described here uses corrosion-fatigue data from one specimen, typically obtained in a few weeks, to predict the complete ripple-load curve between  $K_{ISCC}$  and  $K_{IRLC}$ . The direct experiment approach required many experiments and, for steels, test durations of up to many years.

## 3.0 RESULTS

### 3.1 Analysis of the Ripple-Load Effect

In this investigation, ripple-load cracking is approached as an extreme case of corrosion-fatigue crack growth behavior at very high stress ratios. The desired predictive framework for RLE necessarily involves the interface between SCC and corrosion-fatigue behavior. Thus, the analysis begins with consideration of the relationship between the small amplitude stress-intensity range associated with ripple loading,  $\Delta K$ , the threshold for corrosion fatigue,  $\Delta K_{th}$ , the maximum stress-intensity,  $K_{max}$ , and  $K_{ISCC}$ .

#### 3.1.1 Critical Conditions (for susceptibility)

To define the critical conditions required for a material to exhibit a RLE in marine environment, consider first of all the nature of the interface between stress-corrosion cracking and corrosion fatigue. In Fig. 5, the SCC resistance is indicated by the "static" loading curve, wherein the level of  $K$  represents the initial value of stress-intensity factor associated with a precracked specimen (or structure) which is subjected to a constant load. However, if this constant load is superposed with a "ripple" or small-amplitude cyclic load --- as in the schematic of Fig. 1, then, for a material exhibiting susceptibility to a RLE, cracking resistance appears to be degraded to levels significantly below the "static" threshold  $K_{ISCC}$ , as in Fig. 5. There, the  $K$ -level plotted for the "ripple" curve is actually  $K_{max}^{RL}$ , the maximum level of  $K$  in the ripple-load cycle.

A structure stressed above  $K_{ISCC}$  and under a sustained load is expected to fail by a stress-corrosion cracking mechanism. In this study, our attention was focused on the regime below  $K_{ISCC}$  where propagation of existing cracks and failure are not expected under a constant load condition. Thus, with the presence of small ripples superimposed on a large sustained load, cf. Fig.

1, the maximum stress intensity in the ripple-load cycle,  $K_{\max}^{\text{RL}}$ , was equal to or less than  $K_{\text{ISCC}}$ . That is, the first condition for ripple-load cracking can be set as:

$$K_{\max}^{\text{RL}} \leq K_{\text{ISCC}} \quad (1)$$

Next, from corrosion-fatigue considerations, crack propagation is not going to take place during ripple loading unless  $\Delta K^{\text{RL}}$  in the ripple cycle equals to or exceeds  $\Delta K_{\text{th}}$  or:

$$\Delta K_{\text{th}} \leq \Delta K^{\text{RL}} \quad (2)$$

$$\text{or} \quad \frac{\Delta K_{\text{th}}}{1-R} \leq K_{\max}^{\text{RL}} \quad (2a)$$

Thus, a new parameter,  $K_{\text{IRLC}}$ , the ripple-load cracking threshold below which ripple-load cracking does not occur, can be defined as:

$$K_{\text{IRLC}} = \frac{\Delta K_{\text{th}}}{1-R} \quad (3)$$

Combining (1), (2a), and (3), the conditions for a material to exhibit a ripple-load cracking are:

$$K_{\text{IRLC}} \leq K_{\max}^{\text{RL}} \leq K_{\text{ISCC}} \quad (4)$$

### 3.1.2 Maximum Extent of Degradation

Relation (4) is schematically illustrated in Fig. 6. The ripple effect region, whose upper bound is the stress-corrosion cracking threshold,  $K_{\text{ISCC}}$ , and whose lower bound is the ripple-load cracking threshold,  $K_{\text{IRLC}}$ , defines a "window of susceptibility" in which the ripple-load effect

would be anticipated. The wider the window the more susceptible the material is to ripple-load cracking. In the extreme case, where  $K_{IRLC}$  approaches  $K_{ISCC}$ , the susceptibility window vanishes and no ripple-load effect is expected.

If one considers the difference between the threshold for ripple-load cracking,  $K_{IRLC}$ , and  $K_{ISCC}$ , then the maximum extent of ripple-load degradation can be defined as:

$$\% \text{ degradation} = (1 - K_{IRLC} / K_{ISCC}) \times 100 \quad (5)$$

On the other hand, if conditions of relation (4) are not met, a material will not exhibit susceptibility to a RLE.

### 3.1.3 Quantitative Prediction of Time-to-Failure ( $t_f$ ) Curves

Though the typical logarithmic corrosion-fatigue crack-growth rate curve may well exhibit a more complex shape than shown in the schematic of Fig. 7, nevertheless, it can be approximated in piecewise fashion with power-law segments,

$$\frac{da}{dN} = C_j (\Delta K)^{m_j} \quad (6)$$

Thus, the total number of cycles to propagate a crack to failure follows the piecewise integration (over  $j$  segments) as [20]:

$$(N_p)_j = \int_{(a)_j}^{(a)_f} \frac{da}{C_j [(1-R) P_{\max} f(a, Q)]^{m_j}} \quad (7)$$

where  $P$  is load and  $f(a,Q)$  is a function of crack length ( $a$ ) and structural geometry ( $Q$ ).

Since time-to-failure is simply given by:

$$t_f = \frac{\sum_i (N_p)_j}{\nu} \quad (8)$$

where  $\nu$  is the cyclic frequency, then  $t_f$  can be estimated as:

$$t_f = \frac{1}{\nu} \sum_j \int_{(a_i)_j}^{(a_f)_j} \frac{da}{C_j [(1-R) P_{\max} f(a,Q)]^{m_j}} \quad (9)$$

Though in certain cases  $f(a,Q)$  is sufficiently simple to permit direct integration of Eq. 9 --- such as in the case of a center-cracked tension panel, in general, a numerical integration will facilitate computation.

### 3.2 Ripple-Load Cracking in 5Ni-Cr-Mo-V Steel

Ripple-load cracking and SCC experimental results obtained on the 5Ni-Cr-Mo-V steel are shown in Fig. 8. For tests involving ripple-loading, initial  $K_I$  corresponds to the maximum stress intensity factor in the loading cycle, as shown in Fig. 1.

For the 5Ni-Cr-Mo-V steel, a static  $K_{ISCC}$  was established at 110 MPa  $\sqrt{m}$  (100 ksi  $\sqrt{in.}$ ) based upon multiple long-term tests exceeding 10,000 hours. Ripple-loading data were obtained at  $R$  values of 0.90, 0.95 and 0.975, using "direct experiments" as outlined in Section 2.2. Except for  $R = 0.975$ , all ripple-loading conditions resulted in reduced values of time-to-failure and lower

apparent threshold values. That is, 5Ni-Cr-Mo-V steel is susceptible to RLE under  $R=0.95$  and  $R=0.90$  conditions. For  $R = 0.975$ , the apparent threshold equaled the static  $K_{ISCC}$ . For  $R = 0.95$  and  $0.90$ , the apparent thresholds were  $80$  and  $44 \text{ MPa}\sqrt{\text{m}}$  ( $74$  and  $40 \text{ ksi}\sqrt{\text{in.}}$ ), respectively. As we will see in the upcoming analysis, these thresholds estimated from 4000-hour direct exposures are nonconservative.

As shown in Fig. 8, ripple-loading has a strongly deleterious effect in 5Ni-Cr-Mo-V steel on both apparent threshold levels and on time-to-failure [3]. The apparent threshold levels and time-to-failure under ripple-loading conditions can be analytically predicted from Eqs. 3 and 9, provided that the threshold stress-intensity range and the corrosion-fatigue crack-growth rate corresponding to the particular stress ratio in a similar environment can be established. Vosikovsky has conducted a systematic investigation on the effect of stress ratio on the fatigue crack growth rate in 3.5% NaCl solution on a 5Ni-Cr-Mo-V steel very similar to the one used in the present study [21]. A  $\Delta K_{th}$  value for  $R=0.90$  and  $\nu=0.1\text{Hz}$  is reported to be  $3.10 \text{ MPa}\sqrt{\text{m}}$ .  $\Delta K_{th}$  values for  $R=0.95$  and  $0.975$  can be estimated by extrapolation of Vosikovsky's analytical expression [21] and are approximately  $2.95$  and  $2.875 \text{ MPa}\sqrt{\text{m}}$ , respectively. Based on these measurements and Eq. 3, the threshold values under ripple-loading conditions of  $R=0.90$ ,  $0.95$ , and  $0.975$  are analytically predicted to be  $31$ ,  $59$ , and  $115 \text{ MPa}\sqrt{\text{m}}$ , respectively. These predicted values are then compared in Table 3 with the experimentally deduced apparent threshold values (from Fig. 8). As shown in Table 3, under a very small ripple-loading of  $R=0.975$ , the predicted threshold value is greater than  $K_{ISCC}$ . Thus, according to Eq. 4, no RLE is expected as it is in agreement with the experimental results (Fig. 8). For ripple-loading conditions of  $R=0.90$  and  $0.95$ , the predicted threshold values are significantly lower than their experimentally determined counterparts. That is, threshold values based on 4000-hour ripple-load cracking tests are nonconservative. On the other hand, this does not indicate a significant discrepancy between theory and experiment. Rather, as will be shown next, our analysis indicates that the 4000-hr test duration is inappropriately too short.

The time-to-failure curve can be predicted by numerical integration of Eq. 9, provided the corrosion-fatigue crack growth rate curve is established. Again Vosikovsky's crack growth rate data at  $R=0.90$  is used for numerical integration, relative to the identical cantilever bend-bar geometry used in the experimental work. The procedure is quite straight-forward and involves the fitting of power-law equations in different regions of the crack growth rate data and the subsequent integration using Eq. 9. The predicted time-to-failure curve based on Vosikovsky's data at  $R=0.90$  is presented and compared with the experimental data in Fig. 9. As shown in Fig. 9, excellent agreement between predicted curve and actual experimental data is achieved. This agreement confirms the validity of approaching ripple-load cracking as an extreme case of corrosion-fatigue cracking. Each of the open circles indicates a separate direct experiment. The longest direct experiment was run for 8000 hours and failure of the specimen was not observed. The prediction indicates that the true threshold value for ripple loading,  $K_{IRLC}$ , is substantially lower, but a direct experiment duration on the order of 30,000 hours ( $\sim 3.5$  years) would be required to confirm this. Thus, a 4000-hr test for ripple-load threshold is inappropriately short in the case of this alloy.

### 3.3 Ripple-Load Cracking in AISI 4340 Steel

For the AISI 4340 steel, a long-term static  $K_{ISCC}$  value was established at  $33 \text{ MPa}\sqrt{\text{m}}$  ( $30 \text{ ksi}\sqrt{\text{in.}}$ ) [3]. As shown in Fig. 10, superimposed on these  $K_I$  vs. time-to-failure data curve are two ripple-loading tests with  $R = 0.90$  (largest ripple). To define  $\Delta K_{th}$ , corrosion fatigue tests were performed in the present study at  $R=0.90$  on AISI 4340 steel specimens in 3.5% NaCl solution. The  $\Delta K_{th}$  at  $R=0.90$  was found to be  $3.3 \text{ MPa}\sqrt{\text{m}}$ . Substituting this threshold value in Eq. 3, then the threshold level of  $K$ , below which ripple-load cracking will not occur, is estimated to be  $33 \text{ MPa}\sqrt{\text{m}}$ , which is identical to  $K_{ISCC}$  of the AISI 4340 steel. According to the framework predictions of Eq. 4, a ripple-load effect will not occur. As is shown in Fig. 10, this is exactly what happens to AISI 4340 steel under ripple loading ( $R=0.90$ ) [3]. In other words, AISI 4340 steel is

not susceptible to RLE even at  $R = 0.90$ . Thus, the nonsusceptibility of AISI 4340 steel to RLE can be accurately predicted with the proposed framework.

### 3.4 Ripple-Load Cracking in TLP Tendon Pipe Steel

#### 3.4.1 Microstructure in the Base Metal and Weld Region

The fine base metal microstructure of TLP tendon pipe steel is shown in Fig. 11. The weld region microstructure is shown in Fig. 12. As shown in Fig. 12, the center of this multi-pass weld region (fusion zone), which is marked by a pair of notches, consists of very large columnar grains (Fig. 13). The microhardness across the weld region was also obtained and is shown in Fig. 14. The microhardness and thus the strength in the center fusion zone is substantially higher than that in the base metal region. The above observation is typical for the medium strength carbon steels.

#### 3.4.2 Ripple-Load Cracking in the Base Metal and in Weld Region

##### 3.4.2.1 At 20 °C

The ripple-load crack growth kinetics of the base metal and the weld region in a 3.5% aqueous NaCl solution at ambient temperature with a ripple amplitude equal to 5% of the sustained load ( $R=0.90$ ) are compared in Fig. 15. As shown in Fig. 15, the ripple-load crack growth data exhibit a sigmoidal pattern similar to those obtained at lower stress ratios except in the ripple loading case where the transition from the slow and near-threshold crack growth to the instability spans only a few stress-intensity factors. Figure 15 indicates that the base metal and the weld region have similar crack growth rates at any given stress-intensity and may have identical  $\Delta K_{th}$ . That is, crack tip microstructure has little effect on the fatigue crack growth characteristics for the TLP tendon pipe steel at  $R = 0.90$ . The fatigue crack growth threshold stress-intensity factor range

( $\Delta K_{th}$ ) is estimated to be 3.15 MPa $\sqrt{m}$  for both base metal and weld regions in a 3.5% NaCl solution at a stress ratio of 0.90. According to Eq. 3, the ripple-load cracking threshold,  $K_{IRLC}$ , would equal 31.5 MPa $\sqrt{m}$ . That is, below this ripple-load cracking threshold, crack growth in a 3.5% NaCl solution is not expected even under ripple loading with a ripple amplitude equal to 5% of the sustained load. Above  $K_{IRLC}$ , subcritical cracks would grow under ripple loading conditions.

Values of  $K_{ISCC}$  for the base metal and weld regions determined by constant load cantilever bend bar tests in the 3.5% NaCl solution are estimated to be higher than 78 but lower than 93 MPa $\sqrt{m}$ . In the subsequent ripple-load cracking analysis of TLP tendon pipe steel, a lower and more conservative 78 MPa $\sqrt{m}$  is used as the  $K_{ISCC}$  of this steel.

The effect of ripple loading on SCC can be better illustrated by integrating numerically the fatigue data shown in Fig. 15 and by comparing  $K_{IRLC}$  with  $K_{ISCC}$  directly in the same plot. Figure 16 shows the time-to-failure versus applied stress-intensity curves under ripple loading conditions for both base metal and weld regions of TLP tendon pipe steel, obtained by piecewise integration of the fatigue data shown in Fig. 15. As shown in Fig. 16, there are three regions which are separated by  $K_{ISCC}$  and  $K_{IRLC}$ . In Region 3, the maximum applied stress intensity experienced during ripple loading is higher than either  $K_{ISCC}$  or  $K_{IRLC}$ . In this region, cracks will grow by both fatigue and stress-corrosion cracking mechanisms and a superposition model was developed to address the cracking phenomena [22]. Since stress-corrosion crack growth in steels is well recognized, structural failures in this region are less likely because marine structural designers will take it into consideration when they design a new structure. On the other hand, in Region 1, the maximum applied stress intensity is lower than both  $K_{ISCC}$  and  $K_{IRLC}$ . Under such a loading condition, existing cracks in the structure will be non-propagating, even under ripple loads.

Region 2, which is upper-bounded by  $K_{ISCC}$  and lower-bounded by  $K_{IRLC}$ , is more interesting. Since the maximum applied stress intensity is lower than  $K_{ISCC}$ , stress-corrosion cracking is not expected. However, the applied stress intensity is higher than  $K_{IRLC}$  and cracks will grow under ripple-load conditions. As shown in Fig. 16, in the presence of ripple loads ( $R=0.90$ ), the  $K_{IRLC}$  of TLP tendon pipe steel in 3.5% NaCl solution is  $31.5 \text{ MPa}\sqrt{\text{m}}$ . This represents a ripple-load degradation of 60% when compared to  $K_{ISCC}$ . Thus, Region 2 can be termed the ripple-load cracking susceptible region. Because of the possibility of ripple-load cracking, it is suggested that  $K_{IRLC}$  (which is less than half of  $K_{ISCC}$  for TLP tendon pipe steel investigated) be incorporated into the design process whenever a structure is designed to support a large sustained load with possible small load perturbations. One should be particularly careful with the SCC-resistant alloys because there is more room for a drop from their high  $K_{ISCC}$  and because they are more likely to be selected for use in potential ripple loading conditions. Otherwise, a design based only on the sustained load  $K_{ISCC}$  would be nonconservative in this region.

#### 3.4.2.2 At 3 °C

To simulate deep water temperature conditions, ripple-load crack growth kinetics were determined for base metal at 3 °C under ripple loading ( $R=0.90$ ) in 3.5% NaCl solution. Figure 17 shows the comparison of crack growth kinetics obtained at 3 °C and 20 °C. As shown in Fig. 17, in the intermediate  $\Delta K$  region, the crack growth rate under ripple loading at 3 °C is about two times faster than that at 20 °C. In the near threshold region, however, crack growth rates and the threshold stress intensity factor ranges,  $\Delta K_{th}$ , at these two temperatures are almost identical. Therefore, the ripple load cracking threshold,  $K_{IRLC}$ , at 3 °C for this TLP tendon pipe steel is the same as that for 20 °C.

Figure 18 shows the predicted time-to-failure versus applied stress-intensity curve under ripple loading conditions at 3 °C for TLP tendon pipe steel, obtained by piecewise integration of the

fatigue data shown in Fig. 17. Because the crack growth rates are higher at 3 °C, the failure time at similar stress intensity is slightly shorter when compared to that obtained at 20 °C. As shown in Fig. 18, the  $K_{IRLC}$  under  $R = 0.90$  ripple loading at 3 °C is about 60% lower than the  $K_{ISCC}$  (obtained at 20 °C).

#### 4.0 DISCUSSION

It is useful to elaborate somewhat on a number of points related to the predictive methodology offered in this investigation. Table 3 clearly establishes that materials which exhibit greater SCC resistance under static load conditions are far more susceptible to ripple-load degradation. In other NRL studies, we also have demonstrated that in each of the three engineering material families, highly SCC-resistant alloys are more prone to ripple-load degradation than less SCC-resistant alloys [3-8]. The more SCC-resistant 5Ni-Cr-Mo-V steel and TLP tendon pipe steel experience reductions of more than 50% in apparent  $K_{ISCC}$  when they are subjected to a ripple-load condition. On the contrary, the less SCC-resistant AISI 4340 steel exhibits no ripple-load degradation. The significance of this finding is obvious, at least phenomenologically, as a structure designed to take advantage of the high  $K_{ISCC}$  of a highly SCC-resistant material may fail unexpectedly if ripple-load conditions exist. To circumvent this problem, it is suggested that the possibility of ripple loading in the operating environment should be considered early in the design process, and if a ripple condition indeed does exist, the ripple-load cracking threshold,  $K_{IRLC}$ , should be used instead of the static  $K_{ISCC}$  to determine the allowable stress and inspection intervals.

Secondly, it is significant to note that the ripple effect depends strongly on the size or amplitude of the ripple loads. The larger the ripple-load amplitude, the more damaging the ripple effect. As the fatigue crack growth threshold,  $\Delta K_{th}$ , varies with the stress ratio,  $R$ , the ripple-load cracking threshold,  $K_{IRLC}$ , correspondingly varies with  $R$  according to Eq. 3. Thus, while a material may exhibit substantial ripple-load degradation with larger amplitude ripple loading, the same material may show less or even no ripple-load degradation if the existing ripples are smaller. Ripple load cracking tests at various ripple sizes on 5Ni-Cr-Mo-V steel clearly demonstrate this important point. A separate study had also shown that extremely small ripple loads (smaller than

2% of the sustained load) had no effect on the stress-corrosion cracking resistance of peakaged TIMETAL 21S [23].

Material sensitivities to ripple-load degradation, as defined by the contrast in results found in this investigation, pose an intriguing dilemma to the engineer who must select structural materials for performance in a specific environment. It is clearly disconcerting to the engineer to observe that materials which exhibit the greater SCC resistance under static load condition are the same materials which often exhibit the greater sensitivity to ripple-load degradation. For the specific materials and conditions examined in this work, the more SCC-resistant materials, 5Ni-Cr-Mo-V steel and TLP tendon pipe steel, are more prone to ripple-load degradation than the less SCC-resistant high strength AISI 4340 steel. Even though materials with superior SCC resistance exhibit larger ripple load degradation, there are indications, as shown in Table 3, that their  $K_{IRLC}$  values are close to their less SCC-resistant counterpart. Thus, SCC-resistant materials may still be the material of the choice even with the presence of ripple loading. However, in such instances, the ripple-load cracking threshold  $K_{IRLC}$  should be used for the conservative design of structural components.

A few words are also in order regarding the time-to-failure curves. It is significant to note that although the high stress ratio corrosion fatigue data required for the prediction of time-to-failure via Eq. 9 are difficult to obtain from the literature, they may be readily acquired through automated test methods [24]. The predictive framework thus permits the saving of the much greater time and expense associated with the direct experimental determination of such time-to-failure curves, reducing the testing time from years to a couple of months --- with much of that time spent determining near-threshold behavior.

Finally, ripple-load cracking characteristics can be affected by mechanical and environmental parameters. However, many of these are not adequately understood. While this study shows that ripple loading at  $R=0.90$  causes substantial ripple-load degradation of TLP tendon

pipe steel and 5Ni-Cr-Mo-V steel, the effects of larger ripples (say  $R=0.85$  and  $0.80$ , which are relevant to TLP design) on the cracking resistance and the extent of ripple-load degradation on these steels are still lacking. Ripple load frequency, which is known to affect corrosion fatigue crack growth kinetics, should influence ripple load cracking time-to-failure curves, as indicated by Eq. 9.

## 5.0 Summary

- The presence of ripple loads can cause structural failure at a stress intensity significantly below the static  $K_{ISCC}$  threshold. To assure safety from the ripple effect, a new threshold parameter ( $K_{IRLC}$ ) below which ripple-load cracking will not occur is identified and recommended as a design consideration if ripple-load conditions are suspected.
- TLP tendon pipe steel and 5Ni-Cr-Mo-V steel, which exhibit greater SCC resistance under static load conditions, are very susceptible to ripple-load degradation. On the other hand, SCC-susceptible high strength AISI 4340 steel display no damaging ripple-load effects.
- The extent of the ripple-load effect and  $K_{IRLC}$  depend on the size or the amplitude of the ripple. While a material may exhibit no ripple effect under a very small ripple loading, it may experience a substantial ripple-load degradation when subjected to a larger ripple loading condition.
- A predictive framework for the RLE has been developed from concepts and descriptors used in SCC and corrosion-fatigue characterization. Laboratory test results on both RLE-susceptible and nonsusceptible materials confirm the validity of the proposed framework.
- The critical conditions required for the appearance of a ripple-load effect have been defined.
- A mathematical expression has been developed to describe the maximum extent of ripple-load degradation for specific combinations of material/structure and loading conditions.
- A more efficient methodology for the establishment of time-to-failure curves for ripple-load cracking susceptible materials has been developed.
